12 **Abstract**

13   The Waiapu system provides a prototype for investigating the relative

14 importance of wave- versus current-supported gravity flows on shelf deposition. A

15 two-dimensional model was used to represent gravity-driven sediment transport and

16 deposition on the Waiapu shelf, New Zealand, over an annual cycle of storm events

17 and associated Waiapu River floods. The 12-month run, forced by WAVEWATCH

18 III hindcasts and constrained by benthic tripod data, was divided into two portions: a

19 low-energy period (September 2003 to May 2004) with weak waves and currents and

20 low river discharge, and a high-energy period (May to August 2004) with stronger

21 waves and wind-driven currents and more frequent river floods. Model results

22 indicated that during the low-energy period, riverine sediment was trapped between

23 the 20- and 80-m isobaths. During the high-energy period, sediment was deposited

24 obliquely across the shelf between the 60- and 120-m isobaths. The predicted deposit

25 locations for the low- and high-energy portions, respectively, matched well with

26 short- and long-term observed accumulation patterns based on ^{7}Be and ^{210}Pb activity

27 (Kniskern et al., 2009). Significant gravity flows were mainly wave-supported

28 landward of the 60-m isobath, but became increasingly current-supported as wave

29 orbitals decayed in deeper water. Both analytical theory and numerical results showed

30 that wave-supported gravity currents were sensitive to local water depth and favored

31 deposition parallel to isobaths as depth increased. In contrast, current-supported

32 gravity currents were more sensitive to spatial variations in bathymetry, with seaward

33 decreasing slope and embayed isobaths favoring transport convergence. We conclude

34   that the longer term (~100 yr), shelf-oblique mud deposit on the Waiapu shelf is

35   mainly the result of current-supported gravity flows responding to local variations in

36   seabed slope and curvature of isobaths.

40   **1. Introduction**

41   Until the 1990s, sediment gravity flows were largely considered insignificant

42   for the dispersal of riverine sediment across continental shelves because few shelves

43   are steep enough to provide sufficient gravity forces to maintain autosuspension, and

44   few river effluents are turbid enough to directly produce hyperpycnal discharges. This

45   opinion was fundamentally challenged a decade ago by new field observations and

46   hydrodynamic theory, as well as reexamination of existing data, which indicated that

47   gravity flows can occur on more gently sloping continental shelves when waves

48   and/or currents provide sufficient turbulence to develop near-bed hyperpycnal layers

49   by sediment resuspension (Traykovski et al., 2000; Wright et al., 2001).

50   Three prominent examples of shelves impacted by sediment gravity flows are

51   found seaward of the Eel, Po and Yellow Rivers. Physical and geological studies were

52   conducted on the Eel shelf in the late 1990s as part of the STRATAFORM program

53   (Nittrouer, 1999). One of the fundamental conclusions of STRATAFORM was that

54   across-shelf transport of Eel sediment was dominated by wave-supported gravity

55   flows (Ogston et al., 2000; Traykovski et al., 2000; Scully et al., 2002; Harris et al.,

56 2005). EuroSTRATFORM collected observations on the Po subaqueous delta from

57 the winter 2000 to the spring 2003 (Nittrouer et al., 2004). Field and modeling results

58 again showed that wave-supported gravity flows played an important role in moving

59 sediment downslope offshore of the river mouth (Traykovski et al., 2007; Friedrichs

60 and Scully, 2007). The Yellow River is characterized by extremely high sediment

61 concentrations and is one of relatively the few rivers from which hyperpycnal

62 discharge regularly occurs. However, the direct hyperpycnal river flow extinguishes

63 itself very close to the Yellow River mouth, and most of the sediment is initially

64 trapped within near-shore areas (Bornhold et al., 1986; Wright et al., 1990). Based on

65 revised sediment gravity flow theory, Wright et al., (2001) reanalyzed field data

66 collected offshore of the Yellow River in the 1980s and concluded that the turbid

67 flows maintained by tidal currents could potentially move sediment downslope during

68 slack tide when eddy viscosity temporally decreased.

69   Sediment gravity flows can be wave-supported (e.g., off the Po and Eel) or

70 current-supported (e.g., off the Yellow River) based on the main source of turbulence.

71 Wave-supported gravity flows have been well studied in the last decade, in part

72 because they were observed in both the STRATFORM and EuroSTATAFORM

73 projects, and also because bottom orbital velocities can be easily estimated from

74 widely available surface wave parameters. Wave-induced flows are supported by

75 velocity shear associated with wave orbital velocity within the thin wave boundary

76 layer. Reduced shear at the top of the layer restricts the suspension from diffusing

77 upward, potentially leading to very high sediment concentrations. Fluid mud with

78 sediment concentrations as high as 80 kg/m^3 were inferred within the wave boundary

79 layer on the Eel shelf (Traykovski et al., 2000; Wright et al. 2001). The capacity of

80 such flows to hold suspended sediment is limited by a balance between velocity shear

81 and sediment induced stratification as scaled by the Richardson Number (Wright et al.,

82 1999; 2001). Deposition from these flows is then determined by the gradient of

83 near-bed orbital velocity with depth (Traykovski et al., 2000; Scully et al., 2002) and

84 by depth-dependent changes in bed slope (Friedrichs and Scully, 2007).

85   Additional evidence of current-supported sediment gravity flows offshore of a

86 high-load river has been documented recently. Tripod observations collected on the

87 Waiapu mid-shelf, New Zealand (Fig. 1), in 2004 provided the first clear indication

88 that gravity flows supported by wind-driven mean currents could be an important

89 mode of across-shelf sediment dispersal (Ma et al., 2008). In contrast to thin (< 10 cm)

90 and dense (concentration ~10-100 kg/m^3) wave-supported gravity flows, the

91 current-supported gravity flows observed on the Waiapu shelf were significantly

92 diluted (depth-averaged concentration ~ 4 kg/m^3), and extended over a thicker layer

93 of 1~2 m (Ma, 2009). Compared with wave orbital velocities (based on wave buoys or

94 wave hindcasts), near-bed sub-tidal currents are often less predictable. As a result,

95 predicting the locus of deposition caused by current-supported gravity flow has

96 presented additional challenges (Wright and Friedrichs, 2006).

97   The Waiapu shelf is the first site to date where sediment gravity flows

98 supported by wind-driven currents have been documented (Ma et al., 2008). Such

99 flows are likely to be recognized in the future on many other energetic shelves. To

100   better understand the ramifications of such flows, this paper applies a

101   two-dimensional model for wave- and current-supported sediment gravity-driven

102   flows to the Waiapu River shelf. The main objectives of the paper are (i) to determine

103   whether sediment gravity flows may play a key role in forming the muddy deposits on

104   the Waiapu shelf during both low and high energy periods, (ii) to investigate the

105   effects of currents versus waves on gravity flows and resulting shelf deposition, and

106   (iii) to better understand the relative roles of local water depth and spatially varying

107   bed slope in determining the location of depocenters formed by gravity flows.

108

109   **2. Site description**

110   The Waiapu River drains a small mountainous basin ($\sim$1700 km^2),

111   characterized by steep terrain, heavy rainfall ($\sim$2.4 m/yr), unconsolidated soft Tertiary

112   mudstone and siltstone, and historical deforestation. As a result, its sediment yield

113   ($\sim$20,000 T km^2/yr) is among the highest in the world (Milliman and Syvistki, 1992).

114   Its water discharge is episodic over both inter- and intra-annual timescales, and almost

115   all of the discharge is associated with floods brought on by cyclonic storms.

116   Hyperpycnal plumes may occur in the Waiapu system during flood periods, i.e., total

117   suspended solids in the river can exceed 40 kg/m^3 (Mulder and Syvitski, 1995). At the

118   river mouth, fine-grained materials (>90%) dominate the sediment load (Hicks et al.,

119   2000).

120   Due to the small drainage basin of the Waiapu River, the river-ocean system is

121   strongly coupled in that the weather systems that produce heavy rains and river flows

122   also create energetic waves and wind-driven currents in the coastal ocean (c.f.

123   Wheatcroft, 2000). Bottom tripods deployed on the middle shelf (40-60 m) off the

124   Waiapu in 2004 indicated that significant wave height reached 3.5-5 m during storms

125   (Ma et al., 2008). In addition, currents at the tripod sites were observed to be strong,

126   exceeding 1 m/s at the surface and reaching 0.5 m/s near the seabed. Large-scale

127   circulations influence the outer shelf, including the southwestward East Cape Current

128   and northeastward Wairarapa Coastal Current (Chiswell, 2000).

129   The mid-to-outer continental shelf off the Waiapu River mouth is composed of

130   Holocene sediment that is locally over 100 m thick (Orpin et al., 2002), sitting atop up

131   to 1 km of Pleistocene sediments (Lewis et al., 2004). On the Waiapu inner shelf

132   thinner Holocene facies exhibit significant spatial variation, with river-plume and

133   event deposits dominating north and south of the river mouth, respectively (Wadman

134   and McNinch, 2008). On the mid-to-outer shelf the average modern accumulation rate

135   is about 1.5 cm/yr, with the highest accumulation rate at the Holocene depocenter of

136   about 3.5 cm/yr (Kniskern et al., 2009). Event layers have been found in the sediment

137   cores collected on the shelf break at the head of the Ruatoria Indentation, suggesting

138   the Ruatoria Indentation is a potential conduit through which sediment may escape to

139   deeper water (Kniskern et al., 2009).

140   Kniskern (2007) and Kniskern et al. (2009) measured the ^{7}Be and ^{210}Pb excess

141   activities of sediment cores collected throughout the Waiapu shelf in August 2003 and

142   May 2004. The half-life of ^{7}Be and ^{210}Pb are 53 days and 22 years, respectively,

143   hence they are used to infer deposition on the separate time scales of months and

144   decades. Figure 2 displays the [7]Be activities measured in surface sediment in May

145   2004 (Fig. 2a), just before the tripod deployment of Ma et al. (2008), and the

146   long-term accumulation rate based on excess ^{210}Pb profiles (Fig. 2b). The short-term

147   accumulation rate just before May 2004 was highest on the inner shelf (<50 m water

148   depth) but became close to zero on the middle-to-outer shelf, whereas the long-term

149   accumulation trend was reversed in that ^{210}Pb was mainly found seaward of 50 m. The

150   results indicated that rapid deposition occurred adjacent to the Waiapu River mouth in

151   the months leading up to May 2004, but most sediment probably moved seaward

152   across the shelf over longer time scales. Based on X-radiographs of the sediment

153   cores, Kniskern et al. (2009) concluded that long-term sedimentation on the Waiapu

154   shelf was by event deposits related to hyperpycnal flows.

155

156   **3. Theoretical development**

157   *3.1 Governing equations*

158   Integrated vertically over a sediment gravity flow layer, the momentum

159   balance can be represented as a downslope pressure gradient force induced by

160   suspended sediment opposed by an upslope frictional drag (Wright et al., 2001),

161    $$B\sin\alpha = C_D |u_{max}| u_g.$$ (1)

162   In Eq. (1) α ($\approx \sin\alpha \approx \tan\alpha$ for small α in radian units) is the seabed slope, C_D

163   is the frictional drag coefficient (~0.003), and u_g is the depth-averaged velocity of

164   the gravity-driven flow. The quantity u_{max} is the magnitude of the instantaneous

165   velocity at the top of the gravity layer, which can be expressed approximately as

166
$$u_{\max} = \sqrt{u_w^2 + v_c^2 + u_g^2} \,, \tag{2}$$

167 where u_w is the root-mean-square (r.m.s.) amplitude of wave orbital velocity (equal

168 to $2^{1/2}$ times the standard deviation of the instantaneous orbital velocity), u_g is the

169 downslope directed, gravity-driven current speed, and v_c is the speed of the

170 non-gravity driven ambient current, mainly directed along-shelf. The depth-integrated

171 buoyancy anomaly (B) induced by suspended sediment with mass concentration

172 c_s can be estimated as

173
$$B = \rho_s^{-1} g s \int_{Z=0}^{\delta} c_s dz \,, \tag{3}$$

174 in which g is the acceleration of gravity, $s = (\rho_s - \rho_w)/\rho_w$ is the submerged

175 weight of the sediment relative to seawater, ρ_s and ρ_w are the density of the

176 sediment and water, and δ is the turbid layer thickness.

177 A key scaling parameter that controls the capacity of the gravity flow to hold

178 suspended sediment is in the form of a Richardson number (Wright et al., 2001),

179
$$Ri = B/u_{\max}^2 \,. \tag{4}$$

180 It expresses the importance of the stabilizing effects caused by stratification relative to

181 the destabilizing effects induced by velocity shear. Bed stresses induced by intense

182 waves and currents can generate strong bottom turbulence and can also resuspend

183 bottom sediment causing strong stratification. The suppression of turbulence by

184 stratification leads to settling of suspended sediment; but settling out of sediment then

185 reduces stratification, which enhances turbulence once more. This negative feedback

186 keeps Ri in the neighborhood of a critical value (of order $Ri \approx 1/4$), as has been

187 demonstrated by field observations of bottom turbid layers on the Amazon shelf

188   (Trowbridge and Kineke, 1994), Eel shelf (Wright et al., 1999), and Waiapu shelf (Ma

189   et al., 2008).

190   Combining Eqs. (1), (3), and (4) yields the following expressions for u_g and

191   for the depth-integrated sediment concentration for periods when the turbid layer has

192   reached its maximum sediment capacity:

193
$$u_g = \beta \cdot u_{\max} = \beta \cdot \sqrt{\frac{u_w^{\ 2} + v_c^{\ 2}}{1 - \beta^2}} \ , \tag{5}$$

194
$$\int c_s dz = \frac{Ri_{cr}\rho_s}{gs}[\frac{u_w^{\ 2} + v_c^{\ 2}}{1 - \beta^2}], \tag{6}$$

195   where $\beta = Ri_{cr}\alpha/C_D$. Thus the maximum downslope rate of sediment transported by

196   gravity flows can be estimated by as the product of Eqs. (5) and (6):

197
$$Q_g = u_g \int c_s dz = \frac{\rho_s Ri_{cr}^{\ 2}\alpha}{gsC_D}\left(\frac{u_w^{\ 2} + v_c^{\ 2}}{1 - \beta^2}\right)^{3/2}. \tag{7}$$

198   The rate of downslope sediment transport increases with bed slope, α, as well as

199   with the magnitude of wave orbital velocity, u_w, and with the near-bed ambient

200   current speed, v_c. Note that we require $\beta < 1$ for wave- and/or current-supported

201   gravity flows to exist. If $\beta \geq 1$ (i.e., $\alpha \geq C_D/Ri_{cr} \approx 0.012$), the shelf becomes

202   sufficiently steep for gravity flows to become autosuspending (Wright et al., 2001).

203

204   *3.2 Gravity-induced deposition*

205   The rate of deposition is determined by spatial convergence in sediment

206   transport, which is simplified mathematically if one defines *x* as being directed along

207   the downslope streamline being followed by Q_g. Then

208
$$D = -\nabla \bullet \vec{Q}_g = -\frac{\partial Q_g}{\partial x} - \frac{Q_g}{R},$$
(8)

209   where R is the radius of curvature of the local bathymetric contour. Eq. (8) highlights

210   two distinct transport patterns affecting deposition, one due to gradients in the

211   downslope rate of sediment transport ($\partial Q_g/\partial x$), and one due to lateral convergence or

212   divergence of transport streamlines associated with plan-view curvature of isobaths

213   (Q_g/R). If the bathymetric contours are lobate ($R > 0$), then deposition is reduced; if

214   the contours are embayed ($R < 0$), then deposition is increased.

215   In calculating $\partial Q_g/\partial x$ (using the expression for Q_g from in Eq. (7)), it is

216   reasonable to assume that gradients in u_w^2 dominate gradients in v_c^2, since ambient

217   mean currents (v_c) typically decay with water depth much more slowly than bottom

218   wave orbital velocity (u_w). Thus deposition by sediment gravity flows can be

219   approximately re-expressed as:

220
$$D = Q_g \left\{ -\frac{3u_w}{u_w^2 + v_c^2}\frac{\partial u_w}{\partial x} - \frac{1+2\beta^2}{(1-\beta^2)\alpha}\frac{\partial \alpha}{\partial x} - \frac{1}{R} \right\}.$$
(9)

221   Eqs. (7) and (9) together show that when $Ri = Ri_{cr}$, the deposition rate is controlled by

222   the near-bed wave orbital velocity amplitude (u_w), near-bed ambient current speed (v_c),

223   and shelf slope (α). Since wave orbital velocity attenuates strongly with water depth,

224   the first term in the brackets on the right hand side (r.h.s.) of (9) always favors

225   deposition. The second term in the brackets either increases deposition if the

226   across-shelf bathymetric profile is concave upward ($\partial \alpha / \partial x < 0$), or decreases

227   deposition if the profile is convex upward ($\partial \alpha / \partial x > 0$). The third term accounts for

228   lateral convergence or divergence.

229   For wave-dominated conditions over a linearly (or nearly linearly) sloping bed

230   along a relatively straight coastline, i.e., $|\partial u_w/\partial x|$ large with $|\partial \alpha/\partial x|$ and $|1/R|$ small, the

231   first term on the r.h.s. of Eq. (9) will dominate. This is the case to lowest order for the

232   mid-shelf depocenter off the Eel River, where deposition occurs mainly due to u_w

233   decreasing with greater depth (Traykovski et al. 2000; Scully et al. 2002). But if bed

234   slope rapidly decreases with distance offshore, producing a strongly negative $\partial \alpha/\partial x$,

235   then deposition from a wave-supported gravity flow may be dominated instead by

236   changes in bed slope via the second term on the r.h.s. of Eq. (9). This is case off the

237   Po River, where the depocenter is near the roll-over point on the profile the

238   subaqueous delta, i.e., near the point of the most strongly negative $\partial \alpha/\partial x$ (Friedrichs

239   and Scully, 2007).

240   Assuming that the depth-dependence of v_c is small, the sensitivity of sediment

241   deposition to spatial variations in bed slope ($\partial \alpha/\partial x$) increases dramatically for

242   current-supported gravity flows in the absence of waves. For the hypothetical case of

243      $v_c \gg u_w$, Eq. (9) reduces to

244
$$D = \frac{\rho_s Ri_{cr}^{2} \alpha\, v_c^{3}}{gs C_D (1-\beta^2)^{3/2}} \left\{ -\frac{(1+2\beta^2)}{(1-\beta^2)\alpha} \frac{\partial \alpha}{\partial x} - \frac{1}{R} \right\}. \qquad (10)$$

245 We see from Eq. (10) that current-supported gravity flow deposition is not dependent

246   on absolute depth, and, therefore, deposition due to spatially uniform currents can

247   occur deeper than that due to waves. Keeping in mind that β is proportional to bed

248   slope (α), deposition by current-supported flows will occur where $\partial \alpha/\partial x$ is negative

249   and α is relatively large (as long as β remains less than 1). This optimal combination

250   of negative $\partial \alpha/\partial x$ and large α is likely to occur just downslope of the locations where

251 bed slope first begins to decrease with depth, i.e., just downslope of regions of

252 maximum α. Current-induced deposition will be further enhanced where bathymetry

253 is embayed (i.e., where $R < 0$).

254

255 **4. The two-dimensional model**

256 *4.1 Model implementation*

257 The two-dimensional implementation of Eqs. (1) – (8) was developed by

258 Scully et al. (2003) and has been applied successfully on the Eel (Scully et al., 2003)

259 and Po (Friedrichs and Scully, 2007) shelves to represent patterns of muddy flood

260 deposit formation in response to wave-supported gravity flows. In this paper we

261 extend the two-dimensional model to include the effect of significant ambient currents

262 by retaining a spatially uniform but temporally varying value for v_c in Eq. (2). When

263 there is sufficient river-delivered sediment available to allow $Ri=Ri_{cr}$, the model

264 solves the aforementioned equations in rectangular coordinates to predict the

265 maximum possible gravity flow velocity and rate of sediment deposition. If

266 insufficient sediment is available and u_{max} exceeds a threshold value (u_{erode}),

267 previously deposited sediment is eroded from the bed until $Ri=Ri_{cr}$. If sufficient

268 sediment is still unavailable, subcritical gravity flows move downslope according to

269 Eq. (1) without depositing sediment (Scully et al., 2003). For all of the model runs

270 presented in this paper, $Ri_{cr} = 1/4$, $C_d = 0.003$ and $u_{erode} = 0.35$ m/s, the same values

271 used for the Po shelf by Friedrichs and Scully (2007).

272   For the present application, the active model domain covered a region

273   extending along-shore from 11 km northeast of the Waiapu River mouth to 19 km

274   southwest of the river mouth, and from the coastline to offshore near the 170-m

275   isobath of the Ruatoria Indentation (Fig. 1). The domain was composed of 145×127

276   rectangular element grids, and each grid cell represented an area of about 207 m in the

277   along-shelf direction and 193 m in the across-shelf direction. Unsmoothed bathymetry,

278   which is shown in Figure 1, was provided by NIWA (New Zealand National Institute

279   of Water & Atmospheric Research). The shorelines were digitized from a world

280   coastlines database (http://www.ngdc.noaa.gov/mgg/shorelines/shorelines.html), and

281   the water depth along the shoreline was assigned to be zero. Bathymetry was then

282   smoothed in both the along- and across-shelf directions first via a two-dimensional

283   triangle filter and then by a cubic spline on every seventh grid point. Finally, the shelf

284   slopes in the along- and across-shelf directions were calculated based on the smoothed

285   bathymetry.

286   The two-dimensional model was applied to the Waiapu shelf for the 12-month

287   period extending from 1 September 2003 to 31 August 2004. This period was chosen

288   to cover both storm and calm weather seasons, to encompass the observations of

289   sediment accumulation collected by Kniskern (2007) and Kniskern et al. (2009), and

290   to overlap the tripod observations reported by Ma et al. (2008). Wave period and

291   height, shelf current speed, and riverine sediment discharge were the required

292   time-varying model inputs. Since the simulation period was longer than the available

293   tripod observations, hindcast data for wave height, wave period, and wind velocity

294 were derived from the NOAA WAVEWATCH-III global ocean wave model

295 (NWW3). NWW3 is a publicly available, third generation global wave model with a

296 resolution of 1.25^0 longitude and 1^0 latitude (Tolman, 2002). NWW3 wave heights

297 then were calibrated based on wave heights inferred from tripod observations by Ma

298 et al. (2008), and NWW3 winds were related to the observed along-shelf currents. The

299 most reliable tripod data were from May to July 2004; the observed waves and

300 currents were all obtained within this time interval from an Acoustic Doppler

301 Velocimeter (ADV) mounted about 40 cm above the seabed on the tripod at the 60-m

302 isobath (see Fig. 1).

303

304 *4.2 Wave input*

305 Although the NWW3 grid spacing (1.25 by 1 deg) is relatively coarse, the

306 nearest NWW3 node is advantageously located, only 30 km offshore of the Waiapu

307 River mouth (Fig. 1). The NWW3 hindcast reported significant wave height (H_{sig}),

308 whereas the two-dimensional model used r.m.s. wave height ($H_{rms} = H_{sig}/2^{1/2}$). To

309 correct for this and also help compensate for other potential systematic differences,

310 the NWW3 wave heights were multiplied by a constant such that the 90th percentile of

311 all NWW3 wave heights reported from May to July 2004 equaled the 90th percentile

312 of all H_{rms} values (H_{rms90}) observed at the 60-m tripod site (Fig. 3a). H_{rms90} was found

313 by Friedrichs and Wright (2004) to be an appropriate statistic for predicting

314 wave-supported gravity flows offshore of a variety of rivers around the globe. A

315   reasonably strong correspondence was found between observed waves at the tripod

316   and the calibrated NWW3 hindcast with a correlation coefficient of 0.76 (Fig. 3a).

317   Efforts were made to relate NWW3 hindcast wave periods to those observed at

318   the tripod, but no conclusive relationship was found (the correlation was only 0.06).

319   Other researchers (Trembanis et al. 2007) have similarly found that comparisons

320   between NNW3 hindcasts and observations were much better for wave height than for

321   wave period. Following Friedrichs and Wright (2004), we instead estimated wave

322   periods as a function of wave height for the NWW3 hindcast by assuming

323    $$T = C \cdot \sqrt{H_{rms}} \ , \tag{11}$$

324   in which C is a dimensional constant. Assuming the most reliable observations of

325   wave period from our tripod data were from when waves were large (observed $T = 12$

326   s when $H_{rms} = 2.5$ m, see Ma et al., 2008), we used $C = 7.6$ s m$^{-1/2}$. Time-varying r.m.s.

327   near-bed orbital velocity amplitude was then predicted throughout the model domain

328   using a spatially uniform wave height (from the calibrated NWW3 hindcast of H_{rms}),

329   spatially uniform wave period (from Eq. (11)), spatially varying local water depth

330   (from the smoothed bathymetry), and linear wave theory.

331

332   *4.3 Current input*

333   During storms, tidally-averaged currents on the Waiapu shelf were often

334   stronger than wave orbital velocities (Ma et al., 2008). In contrast to the Eel and Po

335   cases, where waves were assumed to dominate during storms, ambient mean currents

336   on the Waiapu shelf could not be neglected in the calculation of u_{max} (see Eq. 2). If

337 one assumes that the along-shelf current (v_c) dominates the across-shelf current, and

338 that v_c is predominantly driven by the along-shelf wind stress, it follows that

339 $$v_c \sim [v_{wind} \times (u_{wind}^2 + v_{wind}^2)^{1/2}]^{1/2}, \qquad (12)$$

340 where v_{wind} and u_{wind} are the along- and across-shelf wind speed. The correlation

341 between the observed along-shelf current and the right-hand-side of Eq. (12) using

342 NWW3 hindcast winds for May to July 2004 was a reasonably strong 0.70.

343   Given this encouraging relationship, the NWW3 winds were converted to

344 along-shelf currents based on a linear regression against Eq. (12), and then the result

345 was multiplied by a constant to ensure that the hindcast currents had the same energy

346 (i.e., sum of the squared current velocities) as the observed v_c (Fig. 3b). Finally, the

347 time-series for along-shelf current velocity was assigned uniformly onto each model

348 grid point without considering energy decay with water depth or possible topographic

349 effects. Note that in the simulations considered here, ambient currents contributed to

350 the carrying capacity of sediment gravity flows, but ambient currents did not advect

351 sediment.

352

353 *4.4 Sediment input*

354   The model assumed that no pre-existing erodible sediment was available on

355 the seabed at the beginning of each model run and that the only source of sediment

356 input was fine-grained material delivered by the river. The sediment discharge

357 time-series for the Waiapu River was provided by NIWA and was calculated by

358 applying the Waiapu rating curve from Hicks et al. (2004) to the water discharge

359   measured by the Gisborne District Council. However, the sediment input to the

360   gravity flow model was set to be only 23% of the amount predicted by the rating

361   curve, based on the sediment budget of Kniskern et al (2009). Using ^{210}Pb

362   accumulation rates for the Waiapu shelf between 40-m and 200-m water depth,

363   Kniskern et al. (2009) could account for just 23% of the sediment discharge predicted

364   by Hicks et al. (2004).

365   Sensible reasons for reducing the fraction of the total sediment load available

366   for gravity flows include the following: (i) The rating curve includes sands, while

367   only fine sediment is transported by the modeled gravity flows. (ii) According to

368   Hicks et al. (2004), the rating curve contains inherent uncertainty on the order of 40%

369   and may overestimate the sediment concentration at high discharge because of the

370   weighting given to concentrations associated with a few very high concentration,

371   extremely high-yield events. (iii) The river gauging station is 20 km upstream from

372   the river mouth. Because of river channel aggradation, the amount of sediment

373   delivered to the Waiapu coastal ocean is likely less than that inferred 20 km upstream.

374   (iv) Some portion of the fine sediment exiting the Waiapu is likely to remain

375   unflocculated, reducing the likelihood of it initially settling near the river mouth. (v)

376   Riverine sediment are dispersed over the Waiapu shelf not only by gravity-driven

377   flow, but also by other mechanisms, such as classical wave-current resuspension,

378   which likely carries significant amount of sediment out of the model domain

379   (Kniskern et al., 2009). (vi) In their application of the two-dimensional gravity flow

380   model to the Po shelf, Friedrichs and Scully (2007) also reduced riverine sediment

381   input to a fraction of that predicted by the Po rating curve (56% in their case) for

382   analogous reasons.

383   Sediment was introduced into the model along the coast as a line source. Two

384   distinct line sources were considered, a base case which decreased sediment input

385   linearly both north and south of the river mouth (Fig. 4), and a second case with

386   spatially uniform input all along the model's landward edge. The southern and

387   northern limits of sediment input (and the extent of the model domain) were set to

388   coincide with coastal promontories that are likely to form a natural littoral cell. The

389   methodology here was again consistent with the approach of Friedrichs and Scully

390   (2007), who examined both spatially uniform and spatially varying line sources off

391   the Po. Based on the bulk density of cores reported by Kniskern et al. (2009), a seabed

392   porosity of 0.6 was used here to estimate the ultimate deposit thickness.

393

394   *4.5 Low and high energy periods*

395   A year-long time-series of waves and currents was generated by applying the

396   methods discussed above to the available NWW3 hindcast. The estimated r.m.s. wave

397   height and along-shelf current velocity from September 2003 to August 2004 are

398   shown in Figures 5a and 5b, based on which the 12-month period can be divided into

399   two portions: 1) a low-energy period (LEP) from early September 2003 to the

400   mid-May 2004, and 2) a high-energy period (HEP) from mid-May to late August

401   2004. During the LEP, mean r.m.s. wave height and current speed were 0.8 m and

402   0.08 m/s, respectively, and only one significant sediment-yield event occurred (Fig.

403   5c). During the HEP, r.m.s. wave height and current speed were 1.3 m and 0.12 m/s

404   on average. Several high discharge events occurred during the HEP, providing

405   abundant sediment to feed gravity-driven flows (Fig. 5c).

406   Given the r.m.s. wave heights in Figure 5a, the ambient currents in Figure 5b,

407   and the relation for wave period given by Eq. (11), it is straightforward to apply linear

408   wave theory to solve for the time-series of depths at which the strength of the ambient

409   mean current, v_c, first exceeded the r.m.s. amplitude of wave orbital velocity, u_w.

410   Since the strength of the total sediment gravity flow velocity is a simple function of

411    $u_w^2 + v_c^2$ (see Eq. 5), it follows that this depth was also approximately the point at

412   which current-supported gravity flows first dominated wave-supported gravity flows.

413   Figure 5d displays daily median values for this cross-over depth. During energetic

414   periods, u_w commonly exceeded v_c down to about 60-m depth. The median depth at

415   which v_c first exceeded u_w for all times with H_{rms} greater than 2 m in height was $h =$

416   61.8 m.

417

418   **5. Base Case Results**

419   *5.1 Predicted versus observed gravity flow velocities*

420   With the wave orbital velocity, current speed, and bed slopes known at each

421   grid point, the two-dimensional model solved for across-shelf gravity flow velocity

422   (u_g) as described in Section 4. Modeled u_g at the grid point nearest to the 60-m tripod

423   site in response to calibrated NWW3 forcing was compared with observed u_g in Fig. 6

424   (using observations from Ma 2009). The observed u_g was defined as the near-bed

425   across-shelf velocity from the second bin of the downward-looking Pulse Coherent

426   Acoustic Doppler Profiler (~ 43 cm above the bed) minus the free stream across-shelf

427   velocity from the middle bin of the upward-looking Acoustic Doppler Current Profiler

428   (~ 26 m above the bed) for the period of May to July 2004, when the most reliable

429   tripod data were available.

430   The order of magnitude and frequency of the observed and modeled u_g time

431   series match well (Fig. 6), which is key for successfully reproducing the general

432   nature of the observed sediment deposits during the low- and high-energy hindcasts.

433   The fine-scale time lags between the details of the observed u_g time series and the

434   model calculations forced by NWW3 reflect some discrepancy between the actual

435   ambient waves and currents and those inferred from NWW3 time series.

436

437   *5.2 Deposition during low-energy period*

438   The low-energy portion of the NWW3 hindcast covered 257 days, about 5

439   times the half-life of ^{7}Be. This period was divided into 10 segments, and at the end of

440   each segment the modeled deposit thickness was multiplied by a decay factor so that

441   $$D_{j+1} = D_j \cdot e^{-\Delta t / t_{1/2}},\qquad(13)$$

442   where D_j is the deposit thickness predicted at the end of segment j, D_{j+1} is the deposit

443   thickness saved for the next segment $j+1$, Δt is 25.7 days, and $t_{1/2}$ is the half-life of

444   ^{7}Be (53.3 days). In this way, the final deposit was weighted toward more recent

445   deposition in order to roughly represent the fraction of sediment potentially tagged

446   with actively decaying ^{7}Be. Finally, the LEP deposit thickness was normalized by its

447   maximum thickness to represent relative ^{7}Be activity on a scale of 0 to 1.

448   Figure 7 displays the predicted ^{7}Be distribution for the LEP. The modeled high

449   activity sediment was almost entirely deposited at water depths shallower than 80 m,

450   with the maximum activity found along the 40-to-50-m isobath. The focusing of the

451   deposit along the 50-m isobath, at least in the region of the tripods, was likely in

452   response to a local maximum in bed slope just landward of that depth (Fig. 8). As

453   discussed in Section 3.2, greatest deposition by sediment gravity flows under low

454   wave conditions tends to occur where steep slopes first stop increasing with distance

455   offshore. This is because a downslope-directed decrease in bed slope favors sediment

456   flux convergence. Deposition during the LEP was generally closer to shore than

457   during the HEP because the depth-dependent wave orbital velocities were small, and

458   even a relatively low sediment supply overwhelmed the wave-supported gravity flow

459   capacity in relatively shallow water.

460   Pockets of high activity deposition during the LEP were somewhat patchy,

461   most likely in response to remaining local irregularities in the smoothed bed slope.

462   This is consistent with the results from Kniskern et al. (2009) who examined the

463   penetration depths of Kasten cores and found that muddy sediment deposits landward

464   of the 80-m isobath were patchy. Deposition south of river mouth in particular may

465   have been concentrated by a subtle bathymetric trough that extends southward from

466   the river mouth near the coast and becomes indistinct toward the mid-shelf (Wadman

467   and McNinch, 2008). Gravity flows are expected to move sediment along the trough,

468   following the local bathymetry (Wadman and McNinch, 2008).

469   The markers (stars, crosses, triangles) superimposed on the predicted LEP

470   deposition (Fig. 7) indicate sites of observed non-zero [7]Be activities from within the

471   model domain based on the May 2004 survey of Kniskern (2007). The highest

472   observed [7]Be activity (shown as stars) generally matched modeled areas of high

473   activity, while medium (crosses) and relative lower activities (triangles) surrounded

474   the isolated depocenters. Both the model results and observations showed that in the

475   short-term (~ 5 months), sediment delivered by the Waiapu River during periods of

476   low energy was mainly trapped between the 20- and 80-m isobaths.

477

478   *5.3 Deposition during high-energy period*

479   The result of the 2-D model calculation for the high-energy period (HEP) is

480   displayed in Figure 9. The main HEP depocenter was elongated and occurred

481   southeast of the river mouth, between 60- and 120-m water depths, trending offshore

482   toward the north, oblique to the shelf bathymetric contours. Its locus (Fig. 9) matched

483   remarkably with that of the observed highest long-term accumulation rate as shown in

484   Figure 2b. Across- and along-shelf profiles of deposition for the HEP base case are

485   shown by solid lines in Figures 10a and 10b. The maximum accumulation calculated

486   by the model for the outer shelf depocenter was about 5 cm (Fig .10a), roughly

487   consistent with the maximum observed long-term accumulation rate of 3.5 cm/yr. In

488   contrast, the HEP base case predicted as much as 10 cm of deposition 8 km southwest

489   of the river mouth (Fig. 10b), over-predicting the long-term observed annual

490   deposition by more than a factor of two. However, Kniskern et al. (2009) also

491   documented the presence of individual, rapidly emplaced flood layers up to 20 cm

492   thick. Local disagreement between observed and modeled thickness could be the

493   result of several factors, with likely candidates including errors in the assumed

494   distribution of riverine sediment input, non-gravity flow resuspension and transport,

495   and localized errors in model bathymetry.

496   The location of the obliquely trending depocenter was just downslope of a

497   likewise obliquely trending maximum in bed slope (Fig. 8). Thus deposition on the

498   Waiapu shelf during the HEP was accentuated where bed slope first started decreasing

499   offshore in a manner consistent with that suggested by the $\partial \alpha / \partial x$ term in Eq. (10).

500   During the HEP there was also a tendency for a secondary depocenter to form along

501   the 65-to-70-m depth contour (Fig. 9), presumably just offshore of the point where

502   u_{max} could no longer transport all the available riverine sediment. Thus the mechanism

503   which formed this secondary line of deposition is consistent with the behavior

504   suggested by the $\partial u_w / \partial x$ term in Eq. (9). The line of first deposition was deeper during

505   the HEP than during the LEP because of the greater transport capacity of the more

506   energetic wave orbitals. Finally, the $1/R$ term in Eqs. (9) and (10) also helps explain

507   enhanced deposition at ~70-m and ~120-m depths at the southwest and northeast ends

508   of the main depocenter. Both these areas of concentrated deposition occurred where

509   the bathymetric contours are embayed, favoring lateral transport convergence.

510   During the HEP simulation, of the 7.5 MT of sediment included in the gravity

511   flow model, about 88% was deposited within the model domain; 10% escaped into the

512   deep sea; 2% went northward out of the model domain; and less than 1% went

513   southward out of the domain. Although this model could not evaluate the fate of

514   sediment that was not associated with gravity flows, model results clearly suggested

515   that it was during high-energy periods that the sediment delivered by the Waiapu

516   River was transported by gravity-driven flows into the long-term shelf depocenter

517   identified by Kniskern et al. (2009).

518

519   **6. Model sensitivity**

520   *6.1 Currents vs. waves*

521   As indicated by Eqs. (9) and (10), currents can compensate for the decay of

522   wave orbital velocity with depth and hence can cause sediment to accumulate farther

523   offshore and in deeper water. The sensitivity of sediment accumulation to

524   current-supported gravity currents was tested by running the 2-D model with and

525   without v_c. Solid and dashed lines in Figures 10(a) and 10(b) display predicted

526   sediment deposition profiles with and without current-supported gravity flows. The

527   across-shelf profile (Fig. 10a) passes through the tripod sites and the northern end of

528   the primary and secondary depocenters in Figure 9. The along-shelf profile Fig. 10b)

529   roughly parallels the 70-m isobath, cutting through the southwest portion of the main

530   depocenter.

531   With strong currents, the location of greatest deposition was centered around

532   115 m, with secondary deposition near 65 m (solid line in Fig. 10a). The deeper

533   depocenter, favored more by current-induced deposition, occurred just offshore of a

534   local maximum in bed slope (α) (Fig. 10e), in a region of where α was decreasing

535   offshore (Fig. 10g). This association of current-induced deposition with $\partial\alpha/\partial x < 0$ is

536   consistent with the arguments presented in Section 5.3. Without currents, however,

537   much more sediment was deposited near 65-m depth (dashed line in Fig. 10a), where

538   the decay of wave orbital velocities with depth caused wave-supported gravity

539   currents to first lose their capacity to carry all of the available riverine sediment.

540   Deposition by wave-supported gravity flows is relatively more sensitive to total depth,

541   while deposition by current-supported gravity flows is relatively more sensitive to

542   seabed slope. This is why the wave-induced deposit more closely paralleled the

543   bathymetry (following a pattern in h), while the current-influenced deposit cut

544   diagonally crossed the bathymetry (following a pattern in α).

545   For the waves only case, the general trend of the along-shelf distribution of

546   deposition (dashed line in Fig. 10b) more closely followed the along-shelf distribution

547   of riverine sediment input (see Fig. 5). In contrast, the along-shelf distribution of

548   deposition for the current-influenced case at ~70-m depth was strongly shifted to the

549   south of the river mouth (solid line in Fig. 10b). This difference can be understood in

550   part by examining the along-shelf distribution of the change in slope with depth (Fig.

551   10h). At 70-m depth north of the river mouth, $\partial\alpha/\partial x$ is positive, whereas at this depth

552   south of the river mouth $\partial\alpha/\partial x$ is generally negative (Fig. 10h). Since $\partial\alpha/\partial x \geq 0$

553   favors bypassing by current-supported gravity currents and $\partial \alpha / \partial x < 0$ favors

554   deposition, the current-influenced case at this depth (solid line) has deposition focused

555   to the south. The wave-only case (dashed line) is more sensitive to absolute depth

556   than to changing bed slope, so deposition at 70 m more-or-less mimics the distribution

557   of sediment supply. However there is still a slight displacement of the wave-only case

558   to the south, suggesting at least a minor sensitivity of wave-induced deposition to bed

559   slope.

560

561   *6.2 Along-shelf curvature of isobaths*

562   Another factor that shifts the along-shelf pattern of deposition away from

563   mirroring the distribution of riverine input is along-shelf curvature of isobaths, i.e.,

564   bathymetry with a finite radius of curvature (see Eqs. 8-10). Unlike the influence of

565   the across-shelf profile, along-shelf curvature of isobaths can lead to lateral flux

566   convergence or divergence. One way to evaluate the effect of curving bathymetry is to

567   examine the component of bed slope along our along-shelf transect (Fig. 10f). From

568   the southern end of the along-shelf transect to about 6 km south of the river mouth,

569   the along-transect slope component tends to decrease overall (i.e., $1/R < 0$), favoring

570   gravity flow convergence. In other words, isobaths in that region are generally

571   embayed (see Fig. 9). But from that point northward in Figure 10f, the along-transect

572   slope at 70-m depth increases (the contours are lobate with $1/R > 0$), favoring gravity

573   flow divergence. (Note that at ~115 m, at the site of the offshore depocenter, the

574   contours are embayed once more, favoring convergence – see Fig. 9).

575   The sensitivity of sediment accumulation to the curvature of isobaths was

576   explicitly tested by re-running the 2-D model for the HEP base case, but with the bed

577   slope in the along-shelf component of the model's rectangular grid set to zero

578   (dot-dashed line in Figs. 10a and 10b). With the bed slope in the direction of the

579   along-shelf transect turned off, the across-shelf distribution of deposition was changed

580   notably in that more sediment was shifted to the shallower depocenter relative to the

581   deeper depocenter (Fig. 10a). This makes sense because the divergent effect of lobate

582   contours was no longer felt at 65 m, and the convergent effect of embayed contours

583   was no longer felt at 115 m. With the along-shelf bed slope set to zero, the along-shelf

584   shelf distribution of deposition at ~70 m was much smoother (Fig. 10b), indicating

585   that much of the patchiness in the base run was likely to do local divergence and

586   convergence associated with bathymetric curvature. In comparing Figures 10b and

587   10d it is clear that local changes in along-shelf slope are correlated to local changes in

588   deposit thickness.

589

590   *6.3 Along-shelf distribution of sediment input*

591   To test the sensitivity of model calculations to the along-shelf input of riverine

592   sediment, the 2-D model was also run using a line source that spread sediment input

593   equally along the coast with the same total sediment load as the base model run

594   (dashed line in Figs. 10c and 10d). Except for the region 10 to 15 km south of the

595   river mouth, the relative thickness and spatial distribution of the resulting deposit was

596   remarkably similar to the base case. This was an encouraging result, because the

597   original along-shelf distribution of riverine sediment input (see Fig. 5) was relatively

598   arbitrary and unconstrained by observations. The deposit resulting from a uniform line

599   source was proportionally thinner from 8 km south to 5 km north of the river mouth

600   because the uniform line source provided less riverine sediment than the base case in

601   that region. The only major change was between 11 and 16 km south of the river

602   mouth, where the locally increased riverine supply combined with embayed contours

603   led to a notably thicker deposit.

604   A key result was that even with uniform sediment input, the main depocenter

605   created by the current-influenced gravity flow model was still in the same general

606   location and was still oblique to the bathymetry, consistent with the observations of

607   Kniskern et al. (2009). This supported the conclusion that subtle aspects of shelf

608   bathymetry played a dominant role in controlling the location and shape of the

609   depocenter.

610

611   *6.4 Total sediment input*

612   The appropriate factor by which to adjust the sediment rating curve for the

613   base model run was weakly constrained. The base run adopted 23% of the total

614   predicted sediment delivery, mainly based on the sediment budget of Kniskern et al.

615   (2009) (see discussion in Section 4.4). To illustrate the impact of varying the total

616   amount of sediment input, another model run was conducted with double the original

617   amount of sediment and the same wave and current conditions as the base case.

618   With double the riverine sediment load, deposition increased proportionally

619   more in shallow water than in deep water (Fig. 10c), because the depth at which the

620   greater sediment supply overwhelmed the capacity of wave-supported gravity flows

621   became shallower. Along the 70-m along-shelf profile, the thickness of the deposition

622   more or less doubled (Fig. 10d), although the base-case peak in deposition 8 km

623   southwest of the river mouth became less dominant. This is consistent with a greater

624   role for wave-supported gravity currents at shallow depths ($< \sim 80$ m) as sediment load

625   was increased. Current-supported gravity currents presumably remained dominant in

626   deeper water, because the shelf-oblique mud deposit remained prominent.

627   Overall, doubling the sediment input relative to the base case caused the

628   model to significantly overpredict the observed thickness sediment deposition on the

629   Waiapu shelf. Nonetheless, the general spatial distribution of deposition remained

630   almost the same. This provides a further support of our main conclusion that shelf

631   bathymetry and associated bed slope strongly influenced the location and shape of the

632   depocenter off the Waiapu River.

633

634   **7. Summary and Conclusions**

635   The Waiapu system provides a prototype for investigating the relative

636   importance of wave- versus current-supported gravity flows on shelf deposition. Such

637   flows are likely to be recognized in the future on many other energetic shelves. In this

638   paper, the two-dimensional gravity-flow model developed by Scully et al. (2003) was

639   applied to the Waiapu shelf by accounting for not only maintenance by waves but also

640   by wind-driven currents. The purpose was to evaluate the likely significance that

641   sediment gravity flows, especially current-supported flows, played in forming muddy

642   shelf deposits. Additional focus was placed on contrasting deposition during high

643   versus low energy periods and on better understanding the relative roles of local water

644   depth versus spatially varying bed slope in determining the location of the deposits.

645   The model and its interpretation was based on analytical theory for

646   critically-stratified gravity flows supported by ambient waves and currents as

647   described by Wright et al. (2001) and as further extended in this paper. Basic model

648   parameters, including the Richardson number (0.25), the bottom drag coefficient

649   (0.003), and the critical velocity for seabed erosion (0.35 m/s) were consistent with

650   those used previously for the Eel (Scully et al., 2003) and Po (Friedrichs and Scully,

651   2007) shelves. To account for support of gravity flows by wind-driven currents, winds

652   hindcast by the NOAA WAVEWATCH III were correlated to shelf current speed.

653   Tripod data collected at 60-m depth from May to July 2004 were used to calibrate the

654   WAVEWATCH III forcing, including wave heights and wind-induced along-shelf

655   currents.

656   The model successfully reproduced the main depositional features of the

657   riverine sediment on the Waiapu shelf by representing both the magnitude and

658   location of the observed muddy deposit. During the fair weather season from

659   September 2003 to May 2004, sediment tended to be trapped between the water

660   depths of 20 and 80 m, consistent with the distribution of ^{7}Be in May 2004 cores as

661   reported by Kniskern (2007). During the storm season in the months of May through

662   August 2004, riverine sediment was transported further offshore, because during this

663   time stronger waves and currents had an increased capacity to carry sediment. The

664   resulting shelf-oblique deposit was consistent with the long-term (100 yr)

665   accumulation pattern as indicated by ^{210}Pb (Kniskern et al., 2009). Analytical theory

666   and numerical results revealed that riverine sediment supply, marine forcing (waves

667   and currents), and bathymetry (depth, slope and along-shelf curvature) were the key

668   factors that influenced patterns of shelf deposition.

669   Currents and waves were shown to play distinct roles in sediment transport

670   and distribution of resulting deposits. Currents tended to dominate the sediment

671   gravity flows in water depths that exceeded about 60 m, where waves became

672   secondary due to rapid decay of orbital velocities. Where waves dominated

673   gravity-driven deposition, the deposits tended to occur at shallower water depths and

674   parallel to the isobaths. This pattern occurred because transport convergence due to

675   waves was driven by the strong dependence of near-bed orbital velocity on absolute

676   depth. In contrast, current-supported gravity flows were not a function of absolute

677   depth and thus could compensate for the decay of wave orbital velocity and move

678   sediment further offshore. Instead, current-supported flows were highly sensitive to

679   the slope of the seabed, and deposition by current-supported gravity currents occurred

680   where bed slope decreased with distance offshore and where isobaths were embayed.

681   Sensitivity tests revealed the relative importance of the magnitude and

682   along-shelf distribution of sediment input. The base case assumed 23% of the river's

683   load was available for shelf deposition (based on the budget of Kniskern et al. 2009)

684   and that a maximum in sediment input occurred directly offshore of the river mouth.

685   Doubling the sediment load or using a uniform along-shelf sediment distribution

686   locally changed the deposit thickness, but the location and oblique trend of the mid- to

687   outer-shelf depocenter remained similar to observations. The relatively insensitivity of

688   the depocenter to sediment load was encouraging since the details of riverine input

689   were poorly constrained.

690   Sediment transport across the Waiapu shelf resulted from a combination of

691   both wave- and current-supported gravity flows. However, we conclude that the

692   longer term (~100 yr), shelf-oblique mud deposit found between the 60- and 120-m

693   isobaths mainly reflects current-supported gravity flows and their response to local

694   variations in seabed slope and bathymetric curvature. Under high-energy conditions,

695   wave-supported flows over the inner shelf transition to current-dominated support as

696   the flows move progressively into deeper water.

827

828   Figure 1. Study area of the Waiapu continental shelf (with bathymetry), northern

829   island of the New Zealand. Two tripods (from Ma et al., 2008) at 40-m and 60-m

830   isobaths are shown as triangles. The domain of 2-D gravity-driven flow model is

831   shown as the bold square, which covers an area of ~29 km × 25 km. The location of

832   the NOAA WAVEWATCH-III global model node used for wind and wave forcing is

833   shown as a square.

834

835   Figure 2. Waiapu shelf coring locations and resulting sediment accumulation patterns

836   based on ^{7}Be (upper, from Kniskern, 2007) and ^{210}Pb (lower, from Kniskern et al.,

837   2009). ^{7}Be indicates that sedimentation over 6-months previous to May 2004 was

838   mainly confined to depths shallower than 80 m, but ^{210}Pb shows a high long-term

839   (100 year) sedimentation rate between the 60-m and 120-m isobaths in a pattern

840   oriented oblique to the isobaths. (Also shown in the lower figure are fault and fold

841   lines delineating the Waiapu River shelf basin from Lewis et al. (2004)).

842

849   mouth for the base-case model run.

850

851   Figure 5. Model inputs during September 2003 to May 2004 low energy period (LEP)

852   and during May to Septebmer 2004 high energy period (HEP): a) Root mean square

853   wave height (H_{rms}) and b) current velocity (v_c) from calibrated NWW3 wave and wind

854   hindcasts; and c) sediment discharge (Q_s) from the Waiapu River based on 0.23 times

855   the rating curve prediction from Hicks et al. (2004) using water discharge provided by

856   the Gisborne District Council. d) Daily median values for the depth at which model v_c

857   first exceeded the r.m.s. amplitude of near-bed wave orbital velocity (u_w).

858

859   Figure 6. Time series of gravity-driven flow at the 60-m tripod site from May to July

860   2004. The solid line is observed velocity; the dashed line is from the two-dimensional

861   model forced by NWW3 output. The observed gravity-driven velocity is defined as

862   the across-shelf velocity observed 43 cm above the bed minus the across-shelf

863   velocity observed 26 m above the bed (data from Ma, 2009). Both time series were

864   passed through a 40 hour low-pass filter.

865

866   Figure 7. Modeled sediment deposition thickness during the low-energy portion (LEP)

867   from September 2003 to May 2004. Also shown is the smoothed bathymetry used to

868   calculate bed slope. The superimposed symbols (also shown in Fig. 2a) are observed

869   non-zero [7]Be activities from Kniskern (2007) (triangle = low, cross = medium, star =

870   high) and a dashed line from Kniskern (2007) delineating the inferred offshore extent

871   of observed ^{7}Be. Inverted triangles indicate locations of Ma et al. (2008) tripods

872

873   Figure 8. Contour plot of the absolute value of bed slope calculated from the

874   smoothed bathymetry (also shown). Inverted triangles indicate locations of Ma et al.

875   (2008) tripods.

876

877   Figure 9. Modeled sediment deposition thickness during the high-energy portion

878   (HEP) from May to August 2004. Also shown are smoothed bathymetric contours (in

879   black) and the Kniskern et al. (2009) observed 3 cm/year sediment accumulation

880   contours (in dark green) from Figure 2b. The two straight grey lines are along- and

881   across-shelf profiles used in Figures 10 and 11. Inverted triangles indicate locations of

882   Ma et al. (2008) tripods.

883

884   Figure 10. Comparisons of base case deposition (solid line) to (a) across- and (b)

885   along-shelf deposition with no current (dashed line) and with zero along-shelf slope

886   (dash-dotted line), and to (c) across- and (d) along-shelf deposition with uniform

887   sediment input (dashed line) and with doubled sediment input (dash-dotted line).

888   Component of bed slope in the direction of (e) across- and (f) along-shelf transect.

889   Across-shelf gradient in bed slope ($\partial\alpha/\partial x$) along the (g) across- and (h) along-shelf

890   transect. Locations of profiles are shown in Figure 9.

891

Figure 1. Study area of the Waiapu continental shelf (with bathymetry), northern island of the New Zealand. Two tripods (from Ma et al., 2008) at 40-m and 60-m isobaths are shown as triangles. The domain of 2-D gravity-driven flow model is shown as the bold square, which covers an area of ~29 km × 25 km. The location of the NOAA WAVEWATCH-III global model node used for wind and wave forcing is shown as a square.
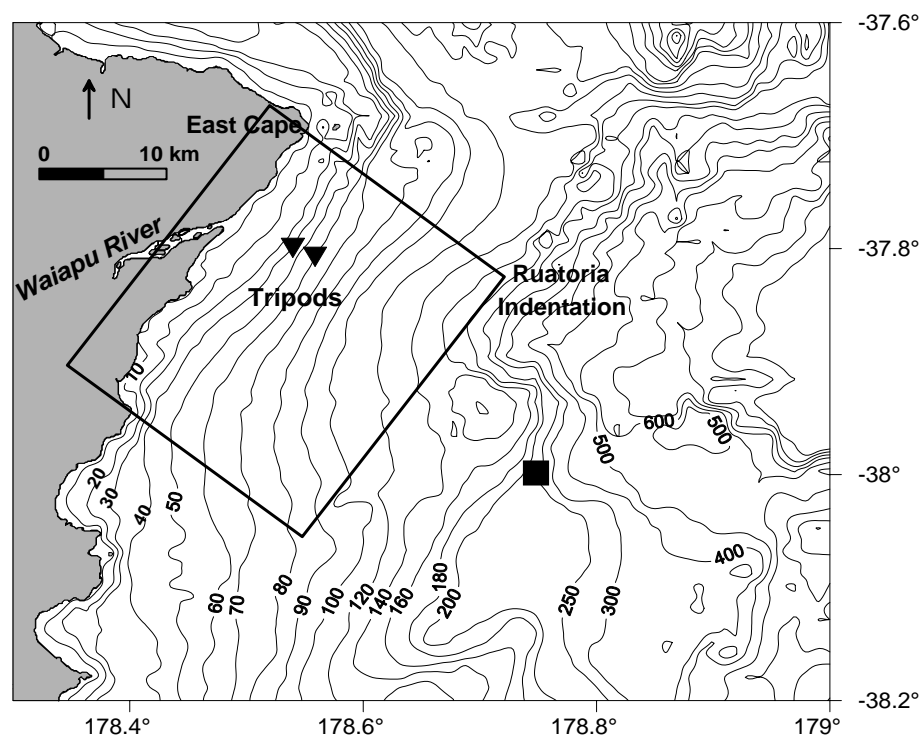

Figure 2. Waiapu shelf coring locations and resulting sediment accumulation patterns based on [7]Be (upper, from Kniskern, 2007) and [210]Pb (lower, from Kniskern et al., 2009). [7]Be indicates that sedimentation over 6-months previous to May 2004 was mainly confined to depths shallower than 80 m, but ^{210}Pb shows a high long-term (100 year) sedimentation rate between the 60-m and 120-m isobaths in a pattern oriented oblique to the isobaths. (Also shown in the lower figure are fault and fold lines delineating the Waiapu River shelf basin from Lewis et al. (2004)).
